54 Hollow fibre oxygenator, assembly containing same and method for making same.

57 A hollow fibre oxygenator assembly containing same, and method for making same wherein a hollow fibre oxygenator element (60) utilizes gas permeable hollow fibres (62) to transfer oxygen into and carbon dioxide from blood flowing around the outside of the fibres (62) while oxygen flows through the fibre lumens. The hollow fibres (62) are arranged in tapes (70) wound helically in layers around a hollow cylindrical core (40). The fibres (62) in each tape (70) angularly cross the fibres (62) in the radially adjacent tape (70), are spaced axially from each other, and are substantially equally spaced radially from the periphery of the core (40) such that the crossing fibres (62) in the radially adjacent layers (70) form small interconnected gaps that permit thin-film radial blood flow with a low blood phase pressure drop and efficient gas transfer.

The oxygenator element (60) is sealed into a shell (12) to form spaced apart oxygen header chamber (48,53) at opposite ends of the core (40) that are sealed from an annular blood chamber (18) surrounding the oxygenator element (60). The shell (12) is provided with inlet and outlet ports (64) for supplying oxygen to one header chamber, through the hollow fibre lumens, and out of the opposite chamber while blood supplied to the core (40) permeates radially outwardly around the hollow fibres (62) and through the layers (70) to the surrounding annular blood chamber (18) as purified and oxygenated blood.

The oxygenator (60) is integrated into a single unit assembly having a top blood reservoir (24) attached to a blood heater (26) that is attached to the blood oxygenator (60) in vertical array.

FIG. 2

FIG. 3

FIG. 8

FIG. 11

DESCRIPTION

HOLLOW FIBRE OXYGENATOR, ASSEMBLY CONTAINING

SAME AND METHOD FOR MAKING SAME

5 Extracorporeal oxygenation of blood during cardiac surgery is a problem of long standing and various types of devices have been developed and used for that purpose since the late 1950's. In 1958, DeWall U.S. Patent 2,972,349 proposed thin walled capillary tubes of silicone rubber for use in a device that flowed
10 blood inside the fibre lumens and oxygen outside the fibres in a gas and liquid tight chamber, but the device did not attain commercial acceptance.

Commercial acceptable blood oxygenators up to the present have comprised bubble oxygenators, disc
15 oxygenators, and flat membrane types. Bubble and disc type oxygenator devices typically employ an open blood chamber in which either oxygen is bubbled directly into a pool of blood or rotating discs expose thin films of blood to an oxygen environment as illustrated
20 in U.S. Patent Nos. 3,675,440 and 3,841,837.

Gas permeable sheet membranes mounted in multiple layered plate and frame filter press devices which supply oxygen to the outer surfaces of a thin blood containing envelope of gas permeable material are typified by U.S.
25 Patent 3,332,746. Another sheet membrane device which employs flattened tubular oxygen containing membranes that transfer oxygen and carbon dioxide to blood flowing over the outer membrane surface is shown in U.S. Patent 4,094,792.

30 The hollow fibre oxygenator of this invention makes use of hollow fibres that carry oxygen in their lumens and transfer oxygen into and carbon dioxide from blood flowing on the outside of the fibres. Research attempts to use hollow fibres with blood flow inside the fibres
35 and oxygen outside the fibres was conducted by The Dow

Chemical Company beginning in 1968 under NHLI Contract PH 43-68-1387 but was abandoned in 1971 in favour of research on the blood-outside hollow fibre concept using fibre winding techniques employed by Dow for hollow fibre reverse osmosis devices. These fibre winding techniques are taught in McLain U.S. Patent 3,422,008 and enable continuous wrapping of fibres on hollow cylindrical supports to form annular mats of fibres. The techniques shown in U.S. Patent 3,422,008 employ a tow of, for example, 16 individual fibres that is laid up as a spiral winding on a cylindrical core as the core rotates with the fibres being looped between spaced apart tubesheets formed by casting resin addition at the ends of the core or at selected spacings along the core. Attempts to use these fibre winding techniques with tows of gas permeable fibres did produce cylindrical devices having the general appearance of the device of Fig. 5 of U.S. Patent 3,422,008.

Certain of the prototype devices did exhibit satisfactory gas transfer characteristics but the good indications could not be consistently repeated due to the lack of control of spacing between individual fibres and non-uniformity of fibre packing density which led to non-uniform flow of blood through the fibre mat. The research was terminated without achieving satisfactory levels of performance relative to commercial blood oxygenators in 1973.

An attempt to control fibre spacing in a hollow fibre oxygenator with blood flow on the outside of the fibres was made in a three year research program conducted at the Medical College of Virginia under NHLI Contract No. PH 43-67-1426. A variety of gas permeable hollow fibres made of polyethylene, silicone rubber, methyl pentene polymers, and mixtures of silicone rubber

and methyl pentene fibres, as well as mixtures of silicone rubber and polycarbonate fibres were evaluated. Various attempts to weave the hollow fibres into an open weave structure that could be laid up in square sheets, or in annular form supported on a cylindrical core were tried, but the program failed and was terminated. Problems still remaining included insufficient fibre strength, elasticity, brittleness, cracking and inability to withstand frictional forces during weaving attempts that result in fibre crushing and flattening.

According to the present invention there is provided a blood oxygenator having an oxygenator element comprising a plurality of hollow gas permeable fibres and a hollow blood permeable core, said fibres overlying the peripheral surface of said core in a plurality of contiguous layers, characterised in that said fibres in each said layer being substantially equally radially distant from said peripheral surface of said core and spaced laterally from each adjacent fibre in said layer, said contiguous layers having the exterior surface of each individual fibre therein contacting the exterior surface of each adjacent fibre in the layer immediately radially outwardly and radially inwardly thereof at an angle between about 30° and about 90°.

The present invention provides in its preferred form a new tape of gas permeable, hollow fibres which comprises a layer of scores, or hundreds, of substantially parallel, gas permeable hollow fibres in a fixed relationship which provides substantially uniform lateral spacing between the fibres in the tape. This tape also includes solid gas impermeable monofilaments on each side edge of the tape and an extremely fine, flexible, continuous, solid monofilament cross thread that is spaced along the length of the tape and maintains the desired lateral hollow fibre spacing without crushing or flattening the fibres at crossover points.

The invention therefore includes an open weave tape of hollow gas permeable fibres for use in wrapping a layered mat on a hollow blood permeable core, characterised in that said tape comprises a layer of a plurality of elongated, substantially parallel hollow gas permeable spaced apart fibres and a solid monofilament defining each of the side edges of said layer, a solid flexible transverse filament woven over and under said adjacent parallel hollow fibres and around the exterior of said solid side edge filament in a continuous traversing pattern along the length of said tape; said transverse filament maintaining said spacing between said hollow fibres without substantially altering the circular cross section of said hollow fibres at crossover points therewith.

The invention further includes a method for making a mat of hollow gas permeable fibres on a hollow blood permeable core which is characterised by the steps of

- 1) providing a blood permeable core,
- 2) providing a tape of hollow gas permeable fibres, said tape comprising a plurality of said fibres arranged in substantially parallel spaced apart and substantially planar relation,
- 3) spirally wrapping said tape on said core to form a layer of said fibres overlying the peripheral surface of said core, the width of said tape and the diameter of said core being selected such that the edge surface of each successive wrap of said tape in said layer is adjacent to the edge surface of the prior wrap so as to substantially maintain said substantially parallel spaced apart relation between said fibres in each said tape, and covering the peripheral surface of said core for the length of said core,
- 4) continuing said wrapping to form overlying layers covering the prior formed said layer by reversing the direction of said spiral such that each tape wrap

positions each said fibre in said overlying layer relative to the adjacent fibre in the underlying layer at an angle between about 30° and about 90°,

5 5) repeating said spiral wrapping to form a plurality of said layers in said relation to each other and securing the axially spaced apart ends of said fibres in each layer to each other and to said core in tube-sheets having co-planar outer end surfaces in which the open lumens of each said fibre terminate.

10 The new blood oxygenator element of this invention comprises a hollow core member fabricated from any blood compatible material such as polypropylene. The core is preferably cylindrical and has a blood permeable wall that serves to support an annular mat of gas permeable;
15 hollow fibre layers laid upon the peripheral surface of the core member. Each layer of hollow fibres on the peripheral surface of the hollow core member is formed by using the above described new tape of this invention. The tape is helically, or spirally, wound on the core
20 such that the side edges of contiguous tapes are immediately adjacent each other to form a continuous layer of hollow gas permeable fibres extending for the full length of the core.

Each layer in the oxygenator element comprises hundreds, or thousands, of hollow fibres that are substantially uniformly spaced from each other, relative to the axis of the core, in a fixed spaced relationship that is substantially maintained during use by virtue of the substantially inelastic nature of the fibres, and the restraining effect of the fine cross thread in the tape, or its equivalent. The successive, contiguous layers of fibres on the core are laid up so that each hollow fibre in each layer is radially equidistant from the peripheral surface of the core. By reversing the angle of spiral, relative to the axis of the core, on each successive layer as the core rotates and tape is applied, the cross over angle at the points of cross over of the individual fibres being applied with the underlying fibres is variably controllable within the range of about 30° and about 90° , and preferably exceeds about 60° . The preferred fibres are microporous polyethylene. After lay up on the core of the desired number of layers of hollow fibres, a resin tubesheet is formed at each end of the core by centrifugal, or dunk potting, and the tubesheets are transversely cut to expose the open lumens of each hollow fibre in the outer end surface of the spaced apart tubesheets. Successive layers of fibres, having a cross over angle above 30° with the contiguous fibres in the overlying and underlying adjacent layers, form a series of substantially uniformly spaced gaps between layers that interconnect in a substantially radial line. These gaps are small and cause the radially outwardly flowing blood to bathe the outer surface of each fibre with a thin film of blood which is gentle and non-harmful to the blood while concurrently causing an efficient gas

exchange through the gas permeable walls of each fibre.

The method of this invention comprises the steps necessary to form the above described new tape of hollow gas permeable fibres, and the steps of winding
5 that tape on a hollow supporting core member to thereby form the new oxygenator element above described.

The new oxygenator element, when incorporated into a cylindrical shell by centrifugally casting a resin
10 tubesheet around the hollow fibres at each end of the core to thereby seal the fibres to each other, to the core and to the inner shell wall, forms the new blood oxygenator device of this invention.

The assembly of this invention comprises a blood
15 reservoir, a blood heater and the new blood oxygenator device of this invention integrated into a single compact, self-supporting, easily handleable unit.

Preferred embodiments of the invention will now be described in detail with reference to the accompanying drawings in which

20 Fig. 1 is a side elevation view of the blood oxygenator device in the preferred orientation during use;

Fig. 2 is a vertical cross-section of the device of Fig. 1 showing the blood oxygenator element integrated
25 into a preferred form of device for use in oxygenating blood;

Fig. 3 is a cross sectional view of the device shown in Fig. 2 taken along the line 3-3 thereof;

30 Fig. 4 is a broken-away portion of a schematic view of the preferred woven form of the tape of this invention;

Fig. 5 is an enlarged perspective view of the lower left hand corner portion of the tape of Fig. 4;

Fig. 6 is a cross sectional view taken along the line 6-6 of Fig. 5;

Fig. 7 is an enlarged schematic perspective view of a plurality of layers of hollow fibres in the oxygenator element of this invention;

5 Fig. 8 is a view illustrating the spiral wrapping of the tape on a cylindrical core;

Fig. 9 is an enlargement of the oxygenator element illustrating the gap location between contiguous layers of hollow fibres and the blood flow path through the element during oxygenation use.

10 Fig. 10 is a vertical rear view of the assembly of this invention;

Fig. 11 is a vertical cross-sectional view of the assembly of Fig. 10 showing a blood reservoir secured on top of a blood heater which is secured to the top of the blood oxygenator device of this invention.

15 Referring to the drawings the hollow fibre blood oxygenator device 10 comprises a shell 12 and a blood oxygenator element generally designated 60. As best seen in Figs. 2 and 3, oxygenator element 60 consists of an annular mat comprising a plurality of overlying layers of hollow fibres 62 supported on the periphery of blood permeable core member 40. Fibres 62 extend for the full length of core 40 and are secured to each other and to core 40 by an axially spaced resin upper tubesheet 42 and lower tubesheet 43 that seal element 20 60 to the upper and lower inner wall surfaces 14, 16, respectively of shell 12 adjacent each of its ends to form outer annular blood chamber 18 that is fluid tight.

25 Tubesheets 42, 43 are generally similar to those employed in hollow fibre separatory elements and devices of the type shown in Mahon U.S. Patent 3,228,867 and may be satisfactorily formed by centrifugal potting techniques described in Geary et al U.S. Patent 3,442,002 using a suitable resin, for example, polyurethane.

35 Alternatively, tubesheets 42 may be formed by

conventional dunk potting techniques now well known to those skilled in the art of hollow fibre devices.

5 Tubesheets 42, 43 terminate in outer end planar surfaces 44, 45, respectively, and the open ends, or lumens 68 of fibres 62 terminate in the planar face of surfaces 44, 45.

10 Tubesheet surface 44 forms with the inner wall 46 of upper header 47 an inlet gas chamber 48 that is gas tight and sealed from blood annulus 18 by overlapping flange 49 that is sealed to shell 12 and tubesheet 42, as shown. Tubesheet surface 45 forms with the inner wall 50 of lower header 52 an outlet gas chamber 53 that is gas tight and sealed from blood annulus 18 by flange 54 that is sealed to shell 12 and tubesheet 43, as shown.

15 Header 47 is provided with inlet gas port 49 which communicates with chamber 48 and during use is attached to a supply gas line, not shown, which normally supplies oxygen, or oxygen containing about 3 to 5 percent carbon dioxide, to the open lumens 68 which lie
20 in the planar surface 44 of tubesheet 42.

Header 52 is provided with outlet gas port 51 that communicates with chamber 53 as shown. It is to be understood, however, that the direction of gas flow, which is preferably downward as shown by arrows 64, may
25 be reversed, if desired. In either event, the gas fed to the inlet chamber enters the lumens of fibres 62 and travel along a spiral path around core 40 and delivers the exit gas to the opposite outlet chamber for discard through means not shown. Header 52 is provided with
30 blood inlet port 55 that is sealed thereto by o-ring 56 and to tubesheet 43, as shown, to deliver blood into blood annulus 59 which lies between the inner surface of core 40 and outer surface 39 of blood flow guide 38. Blood passes through the openings in the wall of core
35 40 radially outwardly through hollow fibre mat 60 to

blood annular space 18 and the oxygenated and purified blood then exits through blood exit port 20. Blood flow through mat 60 will be described in greater detail hereinafter.

5 Shell 12 is provided with a gas vent 13 located adjacent the upper end of blood annulus 18 that serves as a bubble trap vent for air, or other gas, which may become inadvertently introduced into the blood being processed through mat 60. The blood oxygenator 10 when
10 used in configuration shown in Figs. 1 and 2 is preferably tilted slightly from vertical during use, as shown in Fig. 1 to ensure the bubble vent is the uppermost part of blood annulus 18.

 A core vent port 15 communicates through channel
15 17 in blood guide 38 with the upper end of blood core annulus 59 to permit venting of any air, or other gas bubbles, which may collect during use of oxygenator 10. Blood guide 38 is a pointed cylindrical member sealed into tubesheet 42 and to header 47 by o-ring seal 37
20 in the upper snout portion 36, as best seen in Fig. 2.

 Blood oxygenator element, or mat, 60 is formed, in accordance with the method of this invention, by using a tape, generally designated 70, Fig. 8, of gas permeable hollow fibres 62, that is shown in Figs. 4-8
25 inclusive. Referring to Figs. 4 and 5, tape 70 consists of a plurality of scores, or hundreds, or thousands of gas permeable hollow fibres arranged in a layer of long, continuous parallel fibres substantially equally spaced from each other and fixed in position by a solid,
30 flexible, small diameter monofilament cross thread 63 which is woven over and under adjacent fibres, Fig. 6, at a selected tension to avoid any substantial crushing or deforming of the fibres at the cross over points 65.

 Thread 63 may be any blood compatible material
35 that can be formed into a monofilament that is

sufficiently flexible to bend easily over and under the small hollow fibres 62 and which possesses sufficient tensile strength to maintain fibres 62 in their fixed, spaced apart relationship during use. Nylon

5 monofilaments are preferred and satisfactory alternates are polypropylene, impact polystyrene, ABS, or the like. Satisfactory hollow fibres 62 include microporous polyolefins, preferably polyethylene hollow fibres, such as the fibres described in U.S. Patent 4,020,230
10 having a preferred internal diameter of about 200-400 microns, an outside diameter of about 250 to 500 microns, preferably 300-350 microns, and a spacing between the peripheral edges of adjacent fibres of about 50 to about 300 microns, preferably about 100 microns,
15 monofilament 63 is about 10 to 100 denier, preferably about 15 denier. Cross thread 63 is woven into tape 70 as a continuous thread which overlaps each of the side edge, solid, nonporous monofilaments 61, as shown at 66 in Fig. 5, and preferably range from about 6 to 15
20 per inch, preferably about 12 per inch of length of tape 70.

An open weave tape having a continuously traversing monofilament 61 as described is the preferred form of tape 70, but satisfactory results are also obtained with
25 a non-woven tape in which the parallel hollow fibres are maintained in fixed relationship by a thermoplastic monofilament that forms an adhesive bond with each fibre at the crossover point. Such monofilament can be applied as a molten strand which rigidifies and adheres to the
30 hollow fibres 62 at crossover points 65, and sags slightly between the fibres, and may advantageously have sizes approximately similar to those of the above described nylon monofilaments 63.

Side edge monofilaments 61 are solid, high tensile
35 strength filaments having good abrasion resistance that

are selected to have an outside diameter approximately equal to the outside diameter of the hollow fibres in tape 70. Monofilaments 61 successfully withstand the transverse stresses, impact and abrasion wear at turns of the shuttle during weaving and also serve to relieve the longitudinal tensioning forces that are required to maintain fibres 62 in their spaced apart relationship.

Nylon is the preferred material for side edge monofilaments 61 and may vary between about 200 to about 500 microns to correlate with the selected hollow fibres. As an example, in a tape 70 having 160 hollow fibres of microporous polyethylene, each fibre having an outside diameter of about 300 microns, a solid nylon monofilament of 250 micron diameter was used satisfactorily.

Tape 70 may satisfactorily contain a wide range of numbers of hollow fibres that will vary somewhat with hollow fibre size. The number is selected so as to form a tape having a width that is complementary to the outside diameter of core 40 to enable satisfactory spiral winding to form annular mat 60 by using the technique illustrated in Fig. 8. For example, with 325 micron outside diameter microporous polyethylene hollow fibres having a spacing of 100 microns between fibres, an easily handleable tape 70 having a width of about 2.6 inches was formed by using 160 hollow fibres. By using such tape, and a core 40 having a 1.25 inch outside diameter, tape is applied to the core, as the core rotates, by controlling the angle of divergence of the tape from the longitudinal axis of the core such that the side edge filaments 61 lie in immediate adjacency continuously, as successive widths of tape 70 cover the peripheral surface of core 40 for the entire length of the core, before reversal of the angle of the tape to traverse the length of the core in the opposite direction.

It is also satisfactory to position two or more tapes 70 in side by side relationship for simultaneous application to the periphery of core 40 for each axial rotation of the core.

5 It has been found that the optimum annular mat 60 is one which provides contiguous individual fibres in overlying layers of fibres that intersect at an angle in the range of about 45° to 90° and preferably close to 90° and not less than about 30° . As best seen in Fig. 7, gaps 67 are substantially square in shape for fibres 10 62 in contiguous layers which intersect at an angle of substantially 90° and the gap shape becomes an increasingly flattened parallelogram shape as the angle of crossover decreases toward 45° . Fig. 9 illustrates 15 the path of blood flow over the fibres 62 and through gaps 67 as it moves radially along the paths 69 from core annulus 59 to arterial blood annulus 18.

Blood oxygenator element 60 may advantageously be surrounded with a layer of blood filtering screening 20 material such a nylon screen having pores somewhat smaller than the average lateral spacing between hollow fibres in the mat layers, for example, about 20 to 60 microns.

As seen in Figs. 10 and 11 the blood oxygenator 25 element 60 is incorporated into a unitary assembly comprising in vertical array a top blood reservoir generally designated 24, attached at its lower end to the top of a blood heater, generally designated 26, and having blood oxygenator element 60 secured to the lower 30 end of heater 26. As shown in Fig. 11, the shell 12 has been modified to enable attachment of the upper wall portions of shell 12 to the lower end of housing 27 of heater 26. Header 47 has been removed so as to expose the upper surface 44 of tubesheet 42 to the interior core 35 portion of heater 26 which becomes a gas chamber 28 that

receives oxygen through inlet 29 which passes downwardly through hollow fibres 62 and exits through outlet port 35. The shape of blood inlet 55 of the oxygenator device shown in Fig. 2 is modified to exit at a location on the rear surface of the assembly as shown at 30. Blood entering at inlet 30 passes upwardly through blood annular chamber 59, through walls of core 40, through element 60 into blood annulus 18 and the purified arterial blood passes outwardly through port 20 and returns to the patient.

Bubble vents 13 and 15 as shown in Fig. 2 have been modified as to location by adding connecting tube 31 to vent port 32, and the tube 33 to vent port 34, respectively.

Blood heater 26 and blood reservoir 24 may be of conventional construction, or as shown, blood reservoir 26 may have the shape and construction which is described in detail in our separate application which is being filed concurrently herewith and corresponds to U.S. Patent Application Serial No. 350,664.

During use of the assembly 170, Fig. 10, venous blood enters reservoir 24 at inlet 71, passes downwardly through blood outlet 72 into heater 26 and blood, heated or cooled to the desired temperature, exits from blood outlet 73 and is delivered to blood inlet 30 by suitable means, not shown.

.....

CLAIMS

1. A blood oxygenator (10) having an oxygenator
element (60) comprising a plurality of hollow gas
permeable fibres (62) and a hollow blood permeable core
5 (40), said fibres (62) overlying the peripheral surface
of said core (40) in a plurality of contiguous layers
(70), characterised in that said fibres (62) in each
said layer (70) being substantially equally radially
distance from said peripheral surface of said core (40)
10 and spaced laterally from each adjacent fibre (62) in
said layer (70), said contiguous layers (70) having the
exterior surface of each individual fibre (62) therein
contacting the exterior surface of each adjacent fibre
(62) in the layer (70) immediately radially outwardly
15 and radially inwardly thereof at an angle between about
30° and about 90°.

2. A device as claimed in claim 1, characterised
by each layer (70) comprising a plurality of open weave
tapes extending spirally around said core in side-by-
20 side relationship, each tape (70) comprising a plurality
of said fibres (62) extending substantially parallel
and spaced apart, a solid monofilament (61) defining
each of the said edges of said tape (70), a solid
flexible filament (63) woven over and under the adjacent
25 parallel hollow fibres and around the exterior of said
solid side edge fibres (61) in a continuous traversing
pattern along the length of said tape (70); said
filament (63) maintaining the spacing between said
hollow fibres (62) without substantially altering the
30 circular cross section of said hollow fibres (62) at
crossover points therewith.

3. A device as claimed in claim 1 or 2
characterised in that a tubular shell (12) forms a
liquid tight annular chamber (18) around said oxygenator
35 element (60), said fibres (62) terminating in spaced

apart tubesheets (42,43) joining said fibres (62), core (40) and shell (12) together, a gas tight chamber (48, 53) adjacent to the outer end surfaces of each of said tubesheets (42,43) of said element (60), port means (64) communicating with each said gas chamber (48,53),
5 blood inlet means (57) extending through one of said tubesheets (43) and communicating with the core (40) of said element, and blood outlet means (20)

communicating with said liquid tight annular chamber (18).
10 4. A device as claimed in claim 3 characterised in that bubble vent means (13,15) communicate with the upper end portions of each of the blood annular chamber (18) around said element and the interior (59) of said core (40).

15 5. A device as claimed in claim 3 or 4 characterised by an integral, self-supporting unit having an upper blood reservoir (24) attached at its lower end to the upper end of a blood heater (26), said blood heater (26) being attached at its lower end to the
20 upper end of said shell (12).

6. A device as claimed in any preceding claim characterised in that said core (40) is cylindrical, and each said layer (70) extends the full length of said
core (40).

25 7. An open weave tape of hollow gas permeable fibres (62) for use in wrapping a layered mat on a hollow blood permeable core (40), characterised in that said tape comprises a layer (70) of a plurality of elongated, substantially parallel hollow gas permeable
30 spaced apart fibres (62) and a solid monofilament (61) defining each of the side edges of said layer (70), a solid flexible transverse filament (63) woven over and under said adjacent parallel hollow fibres (62) and around the exterior of said solid side edge filament
35 (61) in a continuous traversing pattern along the length

of said tape; said transverse filament (63) maintaining said spacing between said hollow fibres (62) without substantially altering the circular cross section of said hollow fibres (62) at crossover points therewith.

5 8. A device as claimed in any preceding claim characterised in that said gas permeable fibres (62) have an oxygen gas permeability of at least 2×10^{-5} cc (STP) per cm^2 per second per cm Hg transmembrane pressure differential.

10 9. A device as claimed in any preceding claim characterised in that said gas permeable fibres (62) are essentially polyethylene.

15 10. A device as claimed in any of claims 1 to 8 characterised in that said fibres (62) are essentially polypropylene.

11. A method for making a mat of hollow gas permeable fibres on a hollow blood permeable core which is characterised by the steps of

- 20 1) providing a blood permeable core,
- 2) providing a tape of hollow gas permeable fibres, said tape comprising a plurality of said fibres arranged in substantially parallel spaced apart and substantially planar relation,
- 25 3) spirally wrapping said tape on said core to form a layer of said fibres overlying the peripheral surface of said core, the width of said tape and the diameter of said core being selected such that the edge surface of each successive wrap of said tape in said layer is adjacent to the edge surface of the prior wrap so as to
- 30 substantially maintain said substantially parallel spaced apart relation between said fibres in each said tape, and covering the peripheral surface of said core for the length of said core,
- 4) continuing said wrapping to form overlying layers

0089122

covering the prior formed said layer by reversing the direction of said spiral such that each tape wrap positions each said fibre in said overlying layer relative to the adjacent fibre in the underlying layer at an angle between about 30° and about 90° .

5 5) repeating said spiral wrapping to form a plurality of said layers in said relation to each other and securing the axially spaced apart ends of said fibres in each layer to each other and to said core in tube-sheets having co-planar outer end surfaces in which the
10 open lumens of each said fibre terminate.

12. A method as claimed in claim 11 characterised in that said wrapping step 3 includes application of a plurality of said tapes for each rotation of said core.
